(Received 13 April 2018; published 29 June 2018)

We use a combination of x-ray diffraction, total scattering, and quantum mechanical calculations to determine the mechanism responsible for hydration-driven contraction in ZrW_2O_8 . The inclusion of H_2O molecules within the ZrW_2O_8 network drives the concerted formation of new W—O bonds to give one-dimensional $(-\text{W}-\text{O}-)_n$ strings. The topology of the ZrW_2O_8 network is such that there is no unique choice for the string trajectories: the same local changes in coordination can propagate with a large number of different periodicities. Consequently, $\text{ZrW}_2\text{O}_8 \cdot \text{H}_2\text{O}$ is heavily disordered, with each configuration of strings forming a dense aperiodic “spaghetti.” This new connectivity contracts the unit cell via large shifts in the Zr and W atom positions. Fluctuations of the undistorted parent structure towards this spaghetti phase emerge as the key negative thermal expansion (NTE) phonon modes in ZrW_2O_8 itself. The large relative density of NTE phonon modes in ZrW_2O_8 actually reflects the degeneracy of volume-contracting spaghetti excitations, itself a function of the particular topology of this remarkable material.

DOI: [10.1103/PhysRevLett.120.265501](https://doi.org/10.1103/PhysRevLett.120.265501)

Zirconium tungstate, ZrW_2O_8 , is an important material because it harbors a number of useful and counterintuitive mechanical responses to external stimuli. First, on heating, its molar volume *decreases* such that the material is 2% denser at 1050 K than at 0.3 K [1–4]. This negative thermal expansion (NTE) effect is about as strong as the usual positive thermal expansion (PTE) of conventional materials, and so it can be exploited in athermal composites [5–7]. Second, under hydrostatic pressure, ZrW_2O_8 amorphizes unusually easily, transforming into a disordered phase that is denser by more than 20% [8–10]. This switching between crystalline and amorphous states is related to the mechanism exploited for data storage in phase-change chalcogenides [11]. And, third, hydration of ZrW_2O_8 gives the monohydrate $\text{ZrW}_2\text{O}_8 \cdot \text{H}_2\text{O}$, which has a molar volume $\sim 10\%$ smaller than ZrW_2O_8 itself [12,13]. In this sense, the material—which has no appreciable pore network—is nonetheless a kind of “inverse sponge” that shrinks instead of swells when it takes up water. We call this effect “negative hydration expansion” (NHE). NHE is known to occur in anisotropic “breathing” frameworks such as MIL-53 [14,15], but it is rare in cubic systems [16,17]; pore sizes are typically 5–20 Å in all cases. The phenomenon is largely unexplored—and particularly so in ZrW_2O_8 —yet NHE may eventually have applications in counteracting hydration-driven swelling of construction materials (e.g., concretes and clays).

While the mechanism responsible for NHE in ZrW_2O_8 remains unclear [12,13], both NTE and pressure-induced amorphization (PIA) have been studied extensively and are understood to arise from a peculiar phonon spectrum. The material supports an extensive family of low-energy modes with large and negative Grüneisen parameters [18–23]; i.e., their frequencies soften with pressure—the thermodynamic requirement for NTE in cubic systems [6]. Under hydrostatic pressure, the energies of these modes fall to zero [8,24]. Because the modes are distributed throughout the Brillouin zone (BZ), the resulting structural transition is associated with a family of modulation periodicities and, hence, amorphization [10].

Despite the many experimental and computational studies of ZrW_2O_8 , the microscopic origin of its phonon anomalies remains contentious. It is the sheer number of NTE vibrational modes that is difficult to explain: each one appears to involve a remarkably different combination of polyhedral translations, rotations, and distortions [22]. Early indications of the importance of “rigid unit modes” (RUMs) [25–27] have increasingly lost experimental [28,29] and computational [22,23] support, with consensus only emerging regarding the role of polyhedral distortions and the “skipping rope” or “tension” mechanism proposed in Ref. [3].

Intriguingly, hydration switches off NTE in ZrW_2O_8 : $\text{ZrW}_2\text{O}_8 \cdot \text{H}_2\text{O}$ is a conventional PTE material [13,30].

One implication is that the mechanism responsible for NHE saturates the same set of displacements from which NTE arises. Consequently, we sought to determine the structure of $\text{ZrW}_2\text{O}_8 \cdot \text{H}_2\text{O}$, establish a mechanism for NHE, and explore the relationship between NHE and NTE in ZrW_2O_8 itself.

In this Letter, we show that hydration of ZrW_2O_8 proceeds via the concerted formation of one-dimensional strings of new W—O bonds. The topology of the ZrW_2O_8 network is such that there is no unique choice for the trajectory of these strings: the same local changes in coordination can propagate with a macroscopically large number of different periodicities. Each configuration of strings forms a dense “spaghetti” that describes an additional connectivity responsible for contracting the unit cell via surprisingly large shifts in the Zr and W atom positions. So, $\text{ZrW}_2\text{O}_8 \cdot \text{H}_2\text{O}$ is heavily disordered, albeit in a highly correlated fashion. Remarkably, fluctuations of the anhydrous parent towards this spaghetti phase emerge as the key NTE phonon modes in ZrW_2O_8 . Consequently, the density and distribution of NTE modes throughout reciprocal space actually reflect the degeneracy of volume-contracting spaghetti excitations, itself a function of network topology.

The starting point for our study was to prepare and characterize polycrystalline samples of both ZrW_2O_8 and its monohydrate, following the hydrothermal methodologies of Ref. [31]. The corresponding x-ray powder diffraction patterns [Fig. 1] reflect all hydration-driven structural responses noted in earlier studies [12,13]: the crystal symmetry increases on hydration from $P2_13$ to $Pa\bar{3}$, the lattice parameter a decreases from 9.153(3) to 8.876(4) Å, and there is a marked increase in strain-driven peak broadening. We found hydration and dehydration cycles (~ 36 h) to be reversible in all respects, including the appearance and disappearance of strain effects. Rietveld

FIG. 1. X-ray diffraction patterns ($\lambda = 1.54056$ Å) of (a) anhydrous and (b) hydrated ZrW_2O_8 : data in black, fits in red, difference (data – fit) in blue, and reflection positions as tick marks. The fit in (a) is from a Rietveld refinement using the coordinates of Ref. [3]; * = minor impurity. The fit in (b) used our DFT coordinates, with $Pa\bar{3}$ symmetry applied (inset: the corresponding structural model represents the configurational average of a disordered spaghetti).

refinement of the parent ZrW_2O_8 diffraction pattern using the published structure [3] gave an excellent fit, but we encountered the same difficulty noted in [12] of obtaining a structural model for the monohydrate: the scattering density at the Zr and W sites indicated severe positional disorder, and the O atom positions were impossible to determine.

Given the difficulty of directly interpreting the x-ray diffraction pattern of $\text{ZrW}_2\text{O}_8 \cdot \text{H}_2\text{O}$, we used quantum mechanical calculations to determine an energetically-sensible candidate structure for this phase. The structure of ZrW_2O_8 contains a single symmetry-related set of cavities, with each cavity of the correct size to host one H_2O molecule [Fig. 2(a)]. There is one cavity per formula unit, and four formula units per unit cell. The cavities are positioned on the $4a$ Wyckoff sites and coincide with threefold rotation axes of the $P2_13$ space group. Clearly, this point symmetry is incompatible with that of the H_2O molecule, so there is a choice of three possible orientations for each of the four water molecules to be placed in a single unit cell. This situation contrasts that of NH_3 binding in $\text{ZrW}_2\text{O}_8 \cdot \text{NH}_3$, for which NH_3 orientations are ordered and

FIG. 2. (a) The crystal structure of ZrW_2O_8 : Zr in green, W in blue, O in red, and the four cavities of each unit cell in surface representation. (b) DFT geometries of the key structural fragment before (top) and after (bottom) hydration. Note the formation of additional W—O—W bonds. W2...W1 pairs are indicated by a grey arrow; the location of these pairs within the structure is shown in (a). (c) On hydration, neighbouring W2...W1 pairs connect to form W—O—W chains. Note the symmetry-equivalent choices for these new connections (dashed lines). The red cylinders denote the connections made in the DFT ($P2_12_12_1$) structure. (d) The final $P2_12_12_1$ structure, with W—O—W strings shown in grey and H_2O molecules shown in space-filling representation.

$P2_13$ symmetry is maintained [32]—the molecular point symmetry of NH_3 ($3m$) being a supergroup of the $4a$ site symmetry (3) [33]. Instead, the arrangement of H_2O molecules that results in the least severe symmetry lowering gives $P2_12_12_1$ symmetry. We will come to show that $\text{ZrW}_2\text{O}_8 \cdot \text{H}_2\text{O}$ is, in fact, heavily disordered, with $Pa\bar{3}$ symmetry emerging as a configurational average over states related to this $P2_12_12_1$ arrangement we now consider in detail.

Starting with this highest-symmetry H_2O arrangement, we carried out density functional theory (DFT) relaxations at two different levels of theory (the local density approximation (LDA) and the PBESOL0 functional; see [34]). Energy minimization was sensitive to the precise starting positions of the additional H_2O molecules within the framework cavities, yet we were able to identify a series of closely-related low-energy structures with molar volumes smaller by 6–8% than that of ZrW_2O_8 . The corresponding enthalpies of water adsorption were in the range 60–90 kJ mol^{-1} (PBESOL0 functional), indicating strong physisorption [48]. Hence, our calculations are entirely consistent with a NHE effect of the same magnitude as that observed experimentally.

The structure of our lowest-energy $P2_12_12_1$ model for $\text{ZrW}_2\text{O}_8 \cdot \text{H}_2\text{O}$ reveals how hydration brings about a contraction of the unit cell. In this model, each H_2O molecule is chemically bonded to one of the two crystallographically-distinct W atoms [W1 in Fig. 2(b)] along a direction that is no longer parallel to a triad axis of the original unit cell. This new coordination induces a series of coupled rotations and translations of both types of W-centered polyhedra that collectively results in a set of new W—O—W connections. These connections draw the framework in on itself: the terminal W1—O and W2—O bonds of the original structure are forced within bonding distance of nearby W2 and W1 atoms, respectively. Not only does this connectivity reduce the average W...W separation—and in turn the unit-cell volume—but it results in substantial displacement of both Zr and W atoms away from their original sites. Indeed, provided we can account for the $Pa\bar{3}$ crystal symmetry, these displacements are fully consistent with the experiment: Figure 1(b) shows the excellent match between the experimental diffraction pattern and that derived from our DFT coordinates. Moreover, our model accounts for the NTE/PTE switch on hydration: zone-center phonon calculations show a dramatic reduction in the number of NTE modes, with the corresponding coefficient of thermal expansion now positive [34].

Given the existence of this low-energy $P2_12_12_1$ structure, why would the experimental system retain cubic symmetry? We suggest that the key is the existence of a diverging number of different ways of propagating the local changes in coordination identified by our DFT calculations. This degeneracy, we claim, leads to a strongly disordered state. We proceed to describe this state and in turn test our

claims using experimental x-ray pair distribution function (PDF) measurements.

Consider the new W—O—W bonds formed during hydration [Fig. 2(b)]. While there is only one W1 atom accessible to each terminal W2—O bond, there are three equally-spaced W2 atoms that any terminal W1—O bond might approach. These three choices of W2 atoms are related by the same triad axis that is broken by the symmetry of an H_2O molecule. So, in selecting one of three possible states, the particular orientation of each H_2O molecule effectively determines the trajectory of a corresponding W1—O \rightarrow W2 linkage [Fig. 2(c)]. These new W—O—W bonds form one-dimensional strings that in our DFT structure reflect the same $P2_12_12_1$ crystal symmetry of the H_2O molecule arrangements [Fig. 2(d)], but more disordered H_2O arrangements are associated with equally disordered arrangements of W—O—W strings (we will call collections of strings a “spaghetti,” noting the relationship to the “loop” models [49] of, e.g., Coulomb phases [50,51]). Such states are not random. Note that in the DFT structure each W1—O bond approaches only one W2 atom, and each W2 atom is approached by only one W1—O bond. Preserving these local constraints enforces correlations between the new W—O—W bonds formed, and in turn between the orientations of successive H_2O molecules. It can be shown [34] that the number of configurations satisfying these local rules grows exponentially with system size to give a macroscopic number of viable hydration states; the corresponding configurational entropy is $S_{\text{config}} \gtrsim R \ln(9/8)$. Hence, there is an entropic driving force for $\text{ZrW}_2\text{O}_8 \cdot \text{H}_2\text{O}$ to adopt spaghetti states, with the bulk crystal symmetry reflecting the (cubic) configurational average. There is a robust analogy between this model and icelike states on the pyrochlore lattice, which also preserve cubic symmetry [50,52,53].

In order to test the relevance of this spaghetti model to the NHE mechanism of $\text{ZrW}_2\text{O}_8 \cdot \text{H}_2\text{O}$, we proceeded to measure x-ray total scattering data for both ZrW_2O_8 and its hydrate. Such data are directly sensitive to the local structure changes induced by hydration. We then developed a supercell model of a disordered spaghetti state, informed by the DFT structure we have already described, from which an x-ray-weighted PDF might be calculated and compared against experiment.

Our total scattering measurements were performed using a PANalytical Empyrean x-ray diffractometer fitted with an Ag anode ($Q_{\text{max}} = 20 \text{ \AA}^{-1}$) and a GaliPIX3D detector; the corresponding PDFs [54], normalized using GUDRUNX [55], are shown in Fig. 3(a). We were able to model the PDF of ZrW_2O_8 in PDFGUI [56] using the crystal structure of Ref. [3]. By contrast, the $P2_12_12_1$ model for $\text{ZrW}_2\text{O}_8 \cdot \text{H}_2\text{O}$ is capable of fitting convincingly only the very lowest- r region of the corresponding PDF, and it cannot account for the positional disorder evident at distances $r \gtrsim 4 \text{ \AA}$.

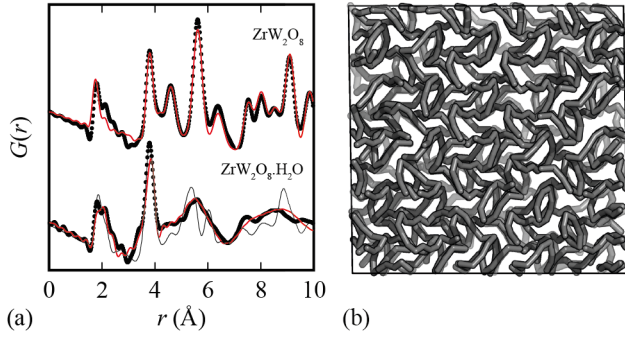

FIG. 3. (a) X-ray PDFs $G(r)$ of anhydrous (top) and hydrated (bottom) ZrW_2O_8 : data as points and fits as lines. For ZrW_2O_8 a satisfactory fit is obtained using the model of Ref. [3] (red lines). For the hydrate, the DFT $P2_12_12_1$ model fits at low r but cannot reproduce the broad oscillations at $r > 4 \text{ \AA}$ (thin black line). Instead, the PDF calculated from our disordered spaghetti model (red line) captures all features. (b) The relaxed GULP model for a $\text{ZrW}_2\text{O}_8 \cdot \text{H}_2\text{O}$ spaghetti configuration as described in the text: only W—O—W linkages are shown, using grey cylinders [cf. Fig. 2(d)].

Because it was not computationally feasible to explore a disordered spaghetti configuration at the DFT level, we used harmonic lattice-dynamical methods, informed by the bonding geometries observed in our $P2_12_12_1$ DFT structure, to generate a $5 \times 5 \times 5$ approximant [57] [Fig. 3(b)]. First, we determined an appropriate disordered spaghetti of self-avoiding W—O—W pathways using a custom Monte Carlo algorithm, guided by the connectivity rules of Fig. 2(c). This spaghetti was used to assign both connectivity and H_2O orientations within a supercell of the $P2_13$ ZrW_2O_8 structure. Atomic positions and unit cell dimensions were then relaxed using the GULP code [34,58], with harmonic potentials constructed from the equilibrium bond distances and angles of our earlier DFT calculation. The cell volume decreased during relaxation, reflecting activation of the NHE mechanism as described above. We consider this GULP-relaxed configuration to be representative of the degree of structural disorder implied by the spaghetti model. The connectivity of the relaxed structure is shown in Fig. 3(b), and the PDF calculated from the full model compared against experiment in Fig. 3(a). The quality of this fit-to-data shows that the displacive disorder introduced by spaghetti W—O—W connectivity can indeed account for the broad oscillations in the experimental PDF.

A necessary consequence of the macroscopic configurational entropy of spaghetti formation on the ZrW_2O_8 lattice is that the corresponding hydration-driven distortions are dense throughout the BZ. Hence, the structure of $\text{ZrW}_2\text{O}_8 \cdot \text{H}_2\text{O}$ reflects a superposition of spaghetti states with arbitrarily large periodicities. Anisotropy vanishes in this limit such that the corresponding global symmetry is cubic, with an average structure given by the projection of all possible distortions onto a single unit cell [Fig. 1(b)].

The large displacements involved account for the substantial crystal strain observed experimentally, and they also account for the difficulty of interpreting even high-quality neutron diffraction data [12]. In turn, proton migration and topological defects in spaghetti state formation account for the introduction of inversion symmetry. Consequently, we conclude that NHE is driven by a degenerate family of “spaghetti”-like lattice distortions modulated with periodicities distributed continuously throughout the BZ.

Having established this mechanism, we sought to determine whether the same distortions that drive NHE are related to the phonons responsible for NTE in ZrW_2O_8 . Published data [23] allow access to the frequencies $\omega(\mathbf{k}, \nu)$, eigenvectors $\mathbf{e}(\mathbf{k}, \nu)$, and Grüneisen parameters,

$$\gamma(\mathbf{k}, \nu) = -\frac{V}{\omega(\mathbf{k}, \nu)} \frac{\partial}{\partial V} \omega(\mathbf{k}, \nu), \quad (1)$$

for each phonon branch ν and wave-vector \mathbf{k} . NTE modes are those for which $\gamma < 0$. By comparing the atomic coordinates of each ZrW_2O_8 framework atom in the anhydrous and hydrated DFT structures, we formed a normalized, mass-weighted displacement vector \mathbf{u} that describes the volume-reducing framework deformations induced by hydration. The projections $c(\mathbf{k}, \nu) = \mathbf{u} \cdot \mathbf{e}(\mathbf{k}, \nu)$ partition these deformations amongst the normal modes; for the $(\mathbf{k} = \mathbf{0})$ DFT structure the $c(\mathbf{k}, \nu)$ necessarily vanish for $\mathbf{k} \neq \mathbf{0}$. Remarkably, we find that 88% of the displacements described by \mathbf{u} can be accounted for in terms of two of the lowest-energy $\mathbf{k} = \mathbf{0}$ NTE modes. The same result is found for zone-center phonons generated by our quantum mechanical calculations [34]. Extending our analysis to wave-vectors $\mathbf{k} \neq \mathbf{0}$ requires access to supercell configurations. So, using the same GULP approach described above, we generated a family of ten different $3 \times 3 \times 3$ spaghetti configurations. For each $\text{ZrW}_2\text{O}_8 \cdot \text{H}_2\text{O}$ configuration, we extracted the corresponding framework displacement vectors \mathbf{u} and projected these onto the phonon eigenvectors $\mathbf{e}(\mathbf{k}, \nu)$ of ZrW_2O_8 for $\mathbf{k} \in \langle (n_1/3), (n_2/3), (n_3/3) \rangle^*$, $n_i \in (0, \pm 1)$. We find that the projections onto the very lowest energy modes (mostly acoustic) account for $\sim 45\%$ of the hydration-driven displacement, and on including all modes with negative Grüneisen parameters, this total projection rises to 87% of the total framework response [Fig. 4] [34].

So, the most important NTE phonon branches are strongly implicated in the NHE response of ZrW_2O_8 , but the question remains of whether the spaghetti displacements invoked for NHE are necessarily involved in the NTE dynamics. The $c(\mathbf{k}, \nu)$ play a crucial role in answering this question: whereas previous studies have focused either on individual collective modes [22] or on the correlated motion of isolated structural fragments [29], the $c(\mathbf{k}, \nu)$ allow us to reconstruct combination NTE modes with intuitive real-space realizations. For example, the $P2_12_12_1$

FIG. 4. Hydration-driven framework displacements in $\text{ZrW}_2\text{O}_8 \cdot \text{H}_2\text{O}$ project strongly onto NTE phonon eigenvectors in ZrW_2O_8 . The average magnitude of projection coefficients c (vertical bars) is shown as a histogram of γ/ω ; nearly 90% of the cumulative projection (blue shaded region) is accounted for by NTE modes.

DFT configuration of Fig. 2(b) gives a framework displacement vector \mathbf{u} that—as we have said—projects almost entirely onto just two zone-center modes ν_1, ν_2 (with $\omega_1 = \omega_2 = 44.1 \text{ cm}^{-1}$ and $\gamma_1 = \gamma_2 = -4.14$). The combination mode $c(0, \nu_1)\nu_1 + c(0, \nu_2)\nu_2$ then describes one specific collective vibration of ZrW_2O_8 contributing to NTE. Crucially, the associated displacement vector $\mathbf{e}' = c(0, \nu_1)\mathbf{e}(0, \nu_1) + c(0, \nu_2)\mathbf{e}(0, \nu_2)$ does indeed involve fluctuations towards the very same spaghetti states assumed by $\text{ZrW}_2\text{O}_8 \cdot \text{H}_2\text{O}$; an animation of this combination mode is provided as Supplemental Material [34]. The same result also holds for the more complex family of NTE modes associated with the $3 \times 3 \times 3$ spaghetti configurations described above [34].

The significance of this result is that the key real-space mechanism for NTE in ZrW_2O_8 is the correlated translation, rotation, and distortion of ZrO_6/WO_4 polyhedra towards the volume-reducing spaghetti states adopted in $\text{ZrW}_2\text{O}_8 \cdot \text{H}_2\text{O}$. The configurational degeneracy of these states—a property of the peculiar ZrW_2O_8 topology—is such that these fluctuations are described by a family of phonons necessarily spread throughout the BZ, with individual spaghetti distortions described by the population of a family of NTE phonons. Consequently, a “spaghetti dynamics” mechanism for NTE in ZrW_2O_8 finally explains (i) why NTE modes are distributed throughout the BZ, (ii) why it is so difficult to interpret individual NTE phonons in isolation, and (iii) how the local polyhedral rotations or translations identified in previous studies [27,29] actually propagate throughout the crystal lattice. Moreover, in determining this mechanism, we have established an unexpected link between the correlated structural disorder associated with NHE, on the one hand, and the property of NTE, on the other hand, that is of significant conceptual importance in the broader context of understanding disorder–property relationships in functional materials [53].
